Final Progress Report

United States Army Research Office, Terrestrial Sciences

Grant Number -- DAAH04-96-1-0036

Principal Investigator -- Dr. Paul R. Bierman

Statement of Problem

Currently, evaluating long-term rates of land surface erosion is a very difficult and uncertain task. Knowing such rates is imperative if land management decisions are to be made responsibly. Only if land managers can compare human-induced rates of surface change, with natural or background rates, can management decision be made cost-efficiently and with the best balance between preservation and use of the land.

In order to further this goal, we determined the background or natural rate at which soil and rock surfaces are eroding at three different sites: the Yuma Proving Ground (Yuma, AZ), the southern Mojave desert (near General Patton's former camp at Iron Mountain), and at Nahal Yael (an intensively studied, hyper-arid basin in the southern Negev of Israel). Such information is useful to land managers who need a context in which to evaluate responsibly the impact of Army mission activities.

Summary of Most Important Results

This funding supported part-time salary, field, and analytic costs for seven students, a faculty member, and a technician to collect and analyze samples from two sites: Yuma Proving Ground, California and the Nahal Yael Research Watershed, Israel. In addition, salary support for Bierman and Clapp was used for the analysis of other related data sets including sediment samples collected from similar landscapes and modelling of complex exposure histories. The results of all of this research are reported in detail by the papers and abstracts listed in the next section.

In summary, our most important findings are:

- At Yuma Proving Ground, we determined that most sediment in upland drainages is
 derived from hillslopes and that rocky outcroppings are the most stable landscape
 features. This suggests that while rocky outcrops may be the landscape features most
 resistant to erosion they will also be the slowest features to recover from human
 impact.
- On the main stem of Yuma Wash, we determined that much of the sediment transported by the Wash is actually derived not from erosion of the highlands but from reworking of the older valley filling alluvium. This finding is important in terms of land management if the need arises to limit the sediment discharge from Yuma Wash. Limiting such discharge will require erosion control not only in the highlands but also in the valley.

DEIC QUALITY INCYECTED 4

At Nahal Yael watershed, we found a similar pattern of stable bedrock and more rapidly eroding hillslopes. We also found that long-term sediment generation rates are substantially less than short term sediment yields as measured by trapping the last 30 years of sediment transported out of the basin behind a retention dam. These findings suggest that short-term measurements of sediment yield may be overestimates. Such a finding has important implications for the design of longlasting engineering works such as dams and sedimentation control structures.
